## Abstract

Furfural is a key bio-derived platform chemical whose reactivity under hydrogen atmospheres affords diverse chemical intermediates. Here, temperature programmed reaction spectrometry (TPRS) and complementary scanning tunneling microscopy (STM) are employed to investigate furfural adsorption and reactivity over a Pt(111) model catalyst. Furfural decarbonylation to furan is highly sensitive to reaction conditions, in particular surface crowding and associated changes in the adsorption geometry: furfural adopts a planar geometry on clean Pt(111) at low coverage, tilting at higher coverage to form a densely packed furfural adlayer. This switch in adsorption geometry strongly influences product selectivity. STM reveals the formation of hydrogen-bonded networks for planar furfural, which favor decarbonylation on clean Pt(111) and hydrogenolysis in the presence of co-adsorbed hydrogen. Pre-adsorbed hydrogen promotes furfural hydrogenation to furfuryl alcohol, and its subsequent hydrogenolysis to methyl furan, while suppressing residual surface carbon. Furfural chemistry over Pt is markedly different to Pd, with weaker adsorption over the former affording a simpler product distribution than the latter; Pd catalyzes a wider range of chemistry, including ring-opening to form propene. Insight into the role of molecular orientation in controlling product selectivity will guide the design and operation of more selective and stable Pt catalysts for furfural hydrogenation.

## Introduction

The development and sustainability of a bio-resource based chemical industry is strongly dependent on new heterogeneously catalyzed processes capable of selectively transforming bio-derived organic molecules into valuable chemical intermediates, platform chemicals, and commercial products. In this respect, fundamental understanding of the underlying mechanistic aspects governing these heterogeneous processes is crucial. Lignocellulosic and oleochemical biomass derived molecules are most attractive due to their abundance and the plethora of products that can be derived from them.

Furfural is one of the most promising renewable platform compounds,<sup>1-4</sup> itself obtainable via the acid catalyzed hydrolysis of C5 sugars such as xylans and xylose.<sup>3,5</sup>

Furfural can be upgraded for a range of applications, finding use as a process agent for generating lubricating oils, and in the flavorings and perfume industry where subtle structural alterations unlock diverse flavorings.<sup>3</sup> However, the majority of furfural (>62%) is hydrogenated to furfuryl alcohol for use as an adhesive, resin or corrosion-resistant coating.<sup>2,6</sup> Furfuryl alcohol is also a chemical building block to many other useful compounds in the fine chemical and pharmaceutical industries as shown in Scheme 1,<sup>7</sup> offering a route to 2-methyl furan, a potential biofuel, or tetrahydrofurfuryl alcohol (B) which can in turn undergo ring-opening hydrogenation to the polymer precursor 1,5-pentandiol(D).<sup>8</sup> While 2-methyl furan production is reported for Pd hydrogenolysis catalysts in the liquid phase,<sup>9-10</sup> it is only observed at high temperature over Pt.<sup>11-15</sup>

Large scale furfural upgrading already occurs in China, South Africa and the Dominican Republic, utilizing ~280,000 tons of furfural per annum.<sup>1</sup> However, current processes rely on a copper chromite catalyst which damages both ecologies and human health.<sup>16-17</sup> This copper chromite catalyst operates at high pressure (up to 30 bar) and high temperature (up to 473 K) affording acceptable selectivity and reasonable activity, but in light of its associated hazards, a replacement catalyst is urgently sought (especially if the transition from a petrochemical to bio-based economy proceeds apace).<sup>2,18</sup>

Furfural hydrogenation has been studied in both the vapor and liquid phase,<sup>11,19-23</sup> and is highly sensitive to reaction conditions over Pt catalysts. In general, liquid phase hydrogenation is conducted at lower temperature than vapor phase studies, hindering direct comparison due to the widely differing products distributions.

**Scheme 1.** Furfural and its derivatives: (A) tetrahydrofuran, (B) tetrahydrofurfuryl alcohol, (C) 1,2-pentanediol and (D) 1,5-pentanediol.

Higher temperature favors ring-opening or total hydrogenation of furfural, while mild conditions favour furfuryl alcohol and furan.<sup>11,20, 24</sup> Liquid phase hydrogenation is complicated by poor hydrogen solubility in the reaction medium, and competitive solvent coupling reactions to form 1° and 2° alcohols (prolific in furfural chemistry),<sup>11-12,14</sup> hence high hydrogen pressures are common; vapor phase studies only require temperature >435 K to vaporize furfural at atmospheric pressure.<sup>25</sup> However, the key factors determining product selectivity and activity are not well-established. Many transition metal catalysts are reported for the hydrogenation of furfural to furfuryl alcohol, including Ni, Pd, Co, Cu, Rh, Ir and Ru.<sup>13, 22-23, 26-29</sup> Platinum has been particularly explored under mild reaction conditions,<sup>11</sup> for vapor phase hydrogenation, with high reaction temperatures yielding a spectrum of small molecules including methyl furan.<sup>20, 30</sup> In contrast, over Pd an array of products forms during liquid phase furfural hydrogenation<sup>10</sup> such as acetals, ketals and polymeric species, in addition to ring-opening products.<sup>31</sup>

Adsorption of unsaturated oxygenates over Cu, Ni, Pd and Pt(111) single crystal surfaces, and Zn adatom modified Pt(111)<sup>32-45</sup> has been the focus of both experimental and theoretical investigations. For furfural, reactively-formed furan (a decarbonylation product from furfural and furfuryl alcohol) behaves differently to molecular furan over Pd(111), the former being more prone to thermal decomposition to

propylene.<sup>39, 46</sup> Density functional theory (DFT) calculations have highlighted multiple reaction pathways for furfuryl alcohol hydrogenolysis over Pd(111) accompanied by the formation of adsorbed water; calculations suggest that the latter by-product hinders furfural hydrogenation over Cu(111).<sup>32</sup> Furfural adsorption and decomposition over Pt(111) and Zn modified Pt(111) has been extensively investigated using temperature programmed desorption (TPD) and high-resolution electron energy loss spectroscopy by Shi and Vohs.<sup>38</sup> They report that furfural adsorbs at low temperatures through the aromatic ring on Pt(111) driving unselective decomposition to CO and H<sub>2</sub> upon heating. Surface modification with Zn adatoms favors furfural adsorption through the carbonyl carbon, and associated ring tilting away from the Pt(111) surface.<sup>38</sup> This molecular re-orientation suppresses thermal decomposition and ring hydrogenation in favor of hydrodeoxygenation (HDO) of the C=O bond.

Here we utilize temperature programmed reaction spectrometry (TPRS) and scanning tunneling microscopy (STM) to elucidate salient features of furfural's adsorption and hydrogenation over Pt(111), and correlate coverage dependent orientation and self-assembly with selectivity towards hydrogenation versus decomposition pathways. Furfural adsorbs in a hydrogen bonded planar network at low coverage, adopting a tilted geometry for a densely packed furfural adlayer. Adsorption geometry and hydrogen co-adsorption influence selectivity towards both evolved products and surface carbon. Pre-adsorbed hydrogen promotes hydrogenation to furfuryl alcohol over decarbonylation to furan, and passivates Pt(111) towards molecular decomposition. These results specifically allow us to discuss the fundamental surface behaviour of furfural that leads to the selectivity of platinum versus other precious metal catalysts, such as palladium, in this important hydrogenation reaction. They also identify the critical importance of surface hydrogen concentration in both selectivity and deactivation as a result of surface coking by carbon. In consequence the present findings help pave the way towards replacement catalysts for the undesirable copper chromite catalyst packages currently employed.

## Experimental

TPRS was conducted in an ultra-high vacuum chamber operated at a base pressure of  $3 \times 10^{-10}$  Torr, equipped with an Omicron 4 grid retarding field analyzer for low energy electron diffraction (LEED) or Auger electron spectroscopy (AES) and a VG 300 quadrupole mass spectrometer whose ionizer was positioned 6 mm from the front face of the sample. The Pt(111) single crystal could be cooled to 140 K and resistively heated to above 1000 K, monitored by a K-type thermocouple attached to the sample. Furfural (Sigma Aldrich, 99%), furan (Sigma Aldrich,  $\geq 99\%$ ), 2-methyl furan (Sigma Aldrich, 99%) and furfuryl alcohol (Sigma Aldrich, 98%) were purified by several freeze-pump-thaw cycles. All organic molecules,  $H_2$  (Energas, 99.99%) and  $O_2$  (Energas, 99.999%) were delivered to the sample by backfilling the chamber to the required pressure. TPD and TPRS measurements were performed with a linear heating ramp of  $9.9 \text{ K s}^{-1}$ . Selectivity calculations (see supporting information) from the mass spectrometry data include corrections for mass spectrometer sensitivity and molecular ionization cross section achieved by admitting a known pressure of each molecule into the vacuum system measuring the intensity of the mass fragments and correcting the pressure gauge reading based on the theoretical ionization cross section. Mass fragments for molecular identification were as follows; furfural (m/z 96 and 39), furan (m/z 68 and 39), furfuryl alcohol (m/z 98, 81 and 39) and methyl furan (m/z 82, 53 and 39). Additional ions were also monitored to identify potential products tetrahydrofuran (m/z 72), tetrahydrofurfuryl alcohol (m/z 102), 2-methyltetrahydrofuran (m/z 82) and propene (m/z 42) however none of these latter molecules were detected from furfural with and without co-adsorbed  $H_2$ . Exposures are quoted in Langmuirs (L), where 1 L is  $1 \times 10^{-6} \text{ Torr s}^{-1}$  and have been corrected for ion gauge sensitivity. STM measurements were carried out in a separate custom built UHV system (base pressure low  $10^{-10}$  Torr) with a commercial STM Aarhus 150 supplied by SPECS using a chemically etched tungsten tip held at 293 K. Furfural molecules were dosed *in situ*. The tunneling bias ( $V_t$ ) is applied to the sample. STM micrographs were processed using the WSxM software<sup>47</sup> by adjustment of the plane and contrast, and appropriate application of moderate Gaussian smoothing. Quoted coverages are based

on estimation of the monolayer point (1 monolayer = 1 ML) from the appearance of a multilayer peak in the TPD data and of the highest density packing arrangement of molecules observed by STM in the high coverage image shown in the results and discussion section.

The single crystal Pt(111) surfaces were cleaned by repeated cycles of Ar<sup>+</sup> (99.999% Messer) sputtering (1 keV, 5  $\mu$ A) for 40 min and annealing at 1000 K. This process was followed by exposure to  $5.5 \times 10^{-8}$  Torr O<sub>2</sub> (Energas, 99.95%) for 25 min at 815 K. The sample was finally annealed to 1000 K. Surface cleanliness was confirmed by LEED, AES or STM.

## Results & Discussion

### Adsorption and reactivity of furfural on Pt(111)

Figure 1a shows TPRS acquired after clean Pt(111) was exposed to 0.15 L of furfural at 140 K. The evolved products were unreacted furfural ( $m/z$  96) and reactively-formed furan ( $m/z$  68), CO ( $m/z$  28), H<sub>2</sub> ( $m/z$  2) and H<sub>2</sub>O ( $m/z$  18). 72% of the adsorbed furfural desorbed intact (main peak at 227 K with a smaller more strongly bound feature at 280 K) while ~22% reacted to furan which desorbed at 291 K. The remainder formed surface carbon (see below), CO and H<sub>2</sub>. The small feature at 280 K in the desorption spectrum of furfural is associated with desorption from step edges of the crystal and it does not increase significantly in intensity as shown in Figure S1a. Note that furfural multilayer peaks on Pt(111) appear at 190 K (Figure S1a and S1b). Note that the 227 K peak in the furan desorption corresponds to furfural which shares a  $m/z$  68 fragment with furan. This  $m/z$  68 fragment is sufficiently weak that we can be confident it is not the main contributor to the furan desorption at 291 K, and indeed the 280 K furfural peak is clearly offset in temperature from the former confirming their different chemical origins. Carbon monoxide desorption due to furfural decarbonylation occurred at 384 K, coincident with the temperature for chemisorbed CO desorption over Pt(111), indicating the former's appearance was desorption-rate limited and hence decarbonylation occurs below 384 K. H<sub>2</sub> desorption from furfural decomposition occurred at 415 K, 488 K and 604 K; all three H<sub>2</sub> desorption peak

temperatures are higher than that of chemisorbed H<sub>2</sub> over clean Pt(111), and hence their appearance was reaction-rate limited (see Figure 1a, Figure S2a and Figure S2b).

Liberation of surface atomic hydrogen from furfural decomposition (Figure 1a) does not lead to any self-hydrogenation products, presumably since the temperature for surface hydrogen formation is higher than the desorption temperature of furfuryl alcohol and methyl furan (Figure S3a and Figure S3b). The hydrogen desorption peak area can be used to estimate the amount of residual carbon on Pt(111) following the temperature ramp as described in the supporting information. We estimate ~6% of the total adsorbed furfural adlayer remains as carbonaceous deposits. Figure 1b presents furfural total conversion and product selectivity as a function of exposure, revealing lower reactivity over crowded surfaces (conversion decreasing from 28% to 9%), while furan selectivity (and the amount of residual carbon) were coverage independent. This fall in furfural conversion and subsequent plateau occurs around 0.45 L, coinciding with saturation of the furfural monolayer (Figure S1a). This saturation exposure is similar to that of 0.6 L reported by Shi and Vohs,<sup>38</sup> with higher exposure rapidly populating multilayers.

**Figure 1.** (a) Raw data showing the desorption products of furfural (0.15 L) on clean Pt(111). (b) The reactivity of the Pt(111) surface at varying furfural exposure.

A microscopic view of furfural on Pt(111) at two different coverages was obtained by STM (Figures 2a, 2b, 2c and Figures 3a, 3b, 3c). Figure 2a shows a representative image for  $\sim 0.5$  ML furfural while Figure 3a that of a saturated furfural adlayer, which also features some multilayer patches. Individual furfural molecules (outlined in blue) are observed to self-assemble in Figure 2a, presumably due to attractive adsorbate-adsorbate interactions. Considering the optimal furfural adsorption geometry calculated by DFT,<sup>36</sup> we assign the bright protrusions in Figure 2a to individual furfural molecules. We further propose that this self-assembly is driven by weak hydrogen bonding between aromatic hydrogens and the carbonyl oxygen: aromatic  $\text{-C-H}\cdots\text{O=C-}$ ,<sup>48</sup> as shown in Figure 2b and 2c. At high coverage (Figure 3a) these bright features change appearance, forming narrow protrusions (example outlined in green). Such protrusions

can be found to be as close as  $\sim 0.36$  nm apart (Figure 3b), much closer than the molecular footprint of a planar furfural molecule. The statistical distribution of the molecular features across the same direction is centered  $\sim 0.36$  nm (Figure 3c), which still cannot be accounted for with a model consisting of planar molecules. The packing density of furfural here is  $\sim 3$  molecules  $\text{nm}^{-2}$  as compared to a maximum density of  $\sim 2$  molecule  $\text{nm}^{-2}$  observed in the submonolayer surface (Figure 2a). This can be attributed to a change in the adsorption geometry towards a strongly tilted molecule, driven by the maximization of the number of molecules in contact with the metal surface.

**Figure 2.** Submonolayer of furfural dosed to a Pt(111) surface kept at 95 K. (a) Overview STM image with a single furfural molecule indicated by the blue circle ( $T = 145$  K,  $V_t = 1.28$  V,  $I_t = 0.12$  nA). The scale bar (black line) is 2 nm. (b) Expanded area from (a), indicated by the blue square, overlaid with an atomistic scale model with furfural in a planar geometry. (c) Model of proposed hydrogen bonded network on the Pt(111).

**Figure 3.** (a) STM image ( $T = 125$  K,  $V_t = -1.58$  V,  $I_t = 0.16$  nA) with high furfural coverage dosed to a Pt(111) surface at 95 K. At coverages without any bare Pt, the line profile (b) across the line (highlighted by a square) indicated in (a) in the same color shows that the molecular features (example outlined in purple) are separated by  $\sim 0.36$  nm. The statistical separation of molecular features across the same direction is displayed in (c). The scale bar (black line) in the STM image is 2 nm.

At 245 K (above the main desorption peak of unreactive furfural), the STM reveals that at submonolayer coverages, some of the structures identified as single furfural molecules packing in the hydrogen-bonded networks are less discernible (Figure 4a). Smaller rounded protrusions enclosed within dotted blue circles whose dimensions are consistent with furan are now seen. At 265 K, above the temperature for furfural desorption and around the onset of that for reactively-formed furan desorption, Figure 4b shows a decrease in the surface coverage of adsorbates.

**Figure 4.** Temperature dependent STM images of the molecular layer on Pt(111) after dosing  $\sim 0.1$  L furfural at 157 K. (a) After heating the sample to 245 K, molecular species consistent with furan, such as the ones in dotted circles can be found ( $V_t = 1.06$  V,  $I_t = 0.10$  nA). (b) After further heating to 265 K some furan molecules have desorbed reducing the surface coverage ( $V_t = -0.45$  V,  $I_t = 0.07$  nA). The scale bar (black line) in the STM images is 2 nm.

### Desorption enthalpies for furfural and furan on Pt(111)

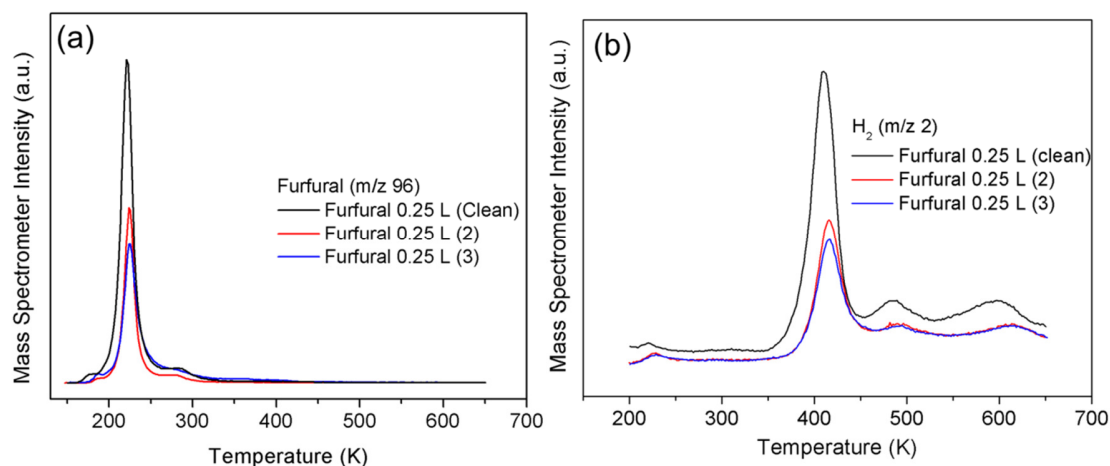

Enthalpies of furfural and furan desorption from Pt(111) were determined from a Redhead analysis,<sup>49</sup> assuming a common pre-exponential factor of  $10^{13} \text{ s}^{-1}$  as widely adopted for organic adsorbates including phenol,<sup>50</sup> benzene<sup>51</sup> and naphthalene.<sup>52</sup> The desorption enthalpy of chemisorbed furfural in the main desorption peak at 227 K was  $\sim 56 \text{ kJ mol}^{-1}$  (Figure 1a). This value appears to be close to the value calculated for the desorption of phenol ( $57 \text{ kJ mol}^{-1}$ ) and cyclopentane ( $58 \text{ kJ mol}^{-1}$ ) on similar Pt(111) surfaces.<sup>50, 53</sup> Furfural desorption from Pd(111) occurs at a far higher temperature 365 K,<sup>39</sup> and hence must be associated with a far greater activation barrier. Redhead analysis for reactively-formed furan from flat laying furan (Figure S4) reveals a desorption enthalpy of  $\sim 73 \text{ kJ mol}^{-1}$ , close to that of unsubstituted aromatics such as benzene with  $68 \text{ kJ mol}^{-1}$  over Pt(111).<sup>51</sup> DFT calculations for furfural on precious metals<sup>39, 54-55</sup> have produced different values depending on the metal used and are sensitive to the inclusion of dispersive interactions.<sup>54</sup> A comparative study suggested that furfural adopts both C=C ring and C=O bonding motifs over Pd, whereas on Pt adsorption only occurs through the C=C ring. The latter adsorption geometry is consistent with the ability of furfural to form the hydrogen-bonded

networks described above. The stronger adsorption of furfural over Pd(111) versus Pt(111) undoubtedly underpins their different reactivity: furfural evolves furan (365 K), CO (460 K) and H<sub>2</sub> (330 K and 410 K) over Pd(111), but also undergoes extensive ring decomposition leading to propylene (385 K).<sup>37,39</sup> In contrast, propylene was not observed over Pt(111) in this work.

### **Investigation and quantification of surface carbon product during furfural desorption from Pt(111)**

As discussed above, furfural adsorption over Pt results in carbon deposition, presenting a major technological drawback to utilizing Pt for large scale furfural hydrogenation. Figures 5a and 5b show consecutive TPRS profiles following a 0.25 L furfural exposure over Pt(111), without cleaning the surface each cycle. Figure 5a shows a 47% drop in furfural desorption intensity between the first and second cycle, with the amount of reactively-formed hydrogen (Figure 5b) reduced by a similar amount (40%). However, between the second and third exposure the furfural and hydrogen desorption intensities only decrease by a further 5% and 3% respectively. These observations demonstrate the number of available adsorption sites has decreased significantly, indicating the accumulation of significant (carbonaceous) residues. Furthermore, the initial decrease in furfural desorption of ~47% between cycles one and two is significantly greater than the proportion of adsorbed furfural calculated to decompose to carbon (~20% from Figure 1b). This suggests that any carbon deposits are likely uniformly distributed across the Pt(111) surface, and hence block a large number of furfural adsorption sites. The formation of carbonaceous deposits from furfural is reportedly favored at 377 K-385 K over Pt catalysts during gas phase hydrogenation,<sup>20, 56</sup> comparable to the desorption temperature for reactively-formed hydrogen (indicative of hydrocarbon decomposition) from furfural over Pt(111) shown in Figure 1a. High furan yields during liquid phase hydrogenation of furfural over Pt nanoparticles is also reported around 343 K,<sup>11</sup> in good agreement with that for the desorption of reactively-formed furan from Pt(111) in this work at 323 K. CO formed through furfural decarbonylation to furan may also be responsible for site-blocking and poisoning of Pt catalysts at

temperatures below that necessary for desorption of the former.<sup>11</sup> Poisoning by carbon laydown typically requires catalyst reactivation (e.g. through calcination) and concomitant loss in metal surface area or changes in particle morphology and hence is often considered irreversible. In contrast, reversible CO poisoning may be mitigated by higher temperature operation.

**Figure 5.** (a) Repeated exposure of furfural (0.25 L), followed by desorption, without surface cleaning in between cycles, showing diminished overall monolayer adsorption feature intensity at 222 K, indicating site blocking by carbon deposits (b) Corresponding decrease in H<sub>2</sub> signal during adsorption/desorption cycles showing a decrease in reactive furfural due to carbonaceous deposits.

### Furfural hydrogenation on Pt(111)

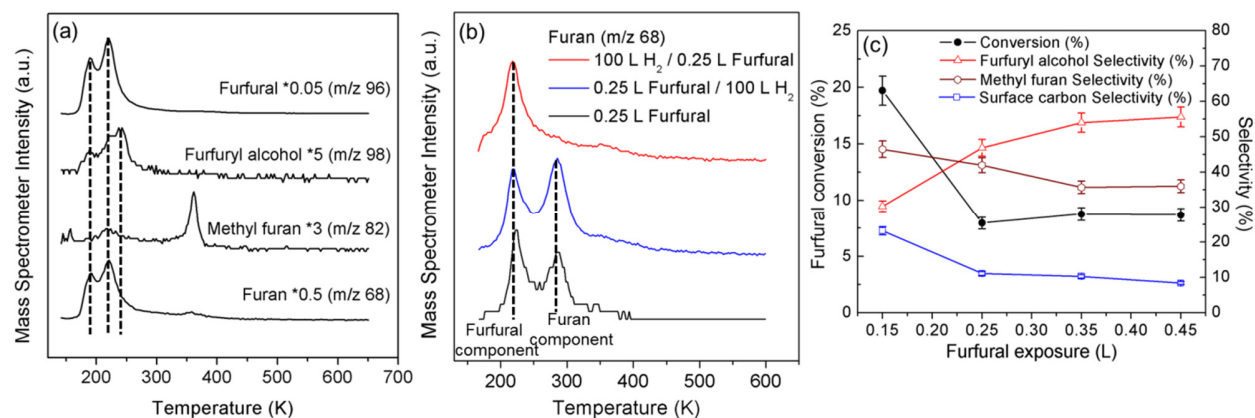

Hydrogen adsorption over clean Pt(111) was first studied by TPRS (Figure S2b) as a function of exposure. The desorption temperature of molecular hydrogen decreased with increasing H<sub>2</sub> exposure in accordance with the expected second order kinetics reported by Gebhardt and Koel.<sup>57</sup> Hydrogen coverages were calculated according to the work of Ertl and coworkers wherein  $\theta H_{\text{sat}}$  was 0.8 ML.<sup>58</sup> Furfural and hydrogen were co-dosed employing a H<sub>2</sub> exposure of 100 L (corresponding to ~0.4 ML) to ensure vacant Pt sites were available for furfural adsorption.

Figure 6a shows data from TPRS of a 100 L H<sub>2</sub> exposure and subsequent 0.35 L furfural exposure at 140 K over Pt(111). Furfural exhibits a multilayer desorption peak ~190 K, and a monolayer desorption at 227 K (Figures 6a and S1b). Similar total yields of reactively-formed furfuryl alcohol (m/z 98) and methyl furan (m/z 82) were observed at 240 K and 360 K respectively, however no furan desorption was observed (Figure 6b). Note that furan, furfuryl alcohol and methyl furan desorptions contain a contribution from furfural (which also exhibits mass fragments at m/z 68, 82 and 98), however the desorption temperatures of reactively-formed furfuryl alcohol and methyl furan differ from that of furfural, but are in close agreement to those observed from their respective molecularly adsorbed species (Figures S3a and S3b) indicating that their appearance is desorption-rate limited. Figure S2a shows the appearance of a low temperature H<sub>2</sub> desorption peak around 306 K, indicated by an arrow, characteristic of the recombinative desorption of molecularly adsorbed hydrogen (Figure S2b). Additional hydrogen desorption must arise from the co-adsorbed furfural and indeed are identical to those observed following furfural adsorption over clean Pt(111) at 415 K, 488 K and 604 K (Figure 1a). As noted in an earlier section furfural auto-hydrogenation over Pt(111) does not occur (Figure 1a), however the observation of furfuryl alcohol in the presence of co-adsorbed hydrogen evidences that furfural hydrogenation is possible over Pt(111) under UHV, providing that a high concentration of hydrogen adatoms is available at a relatively low surface temperature.

Reversing the dosing sequence, such that Pt(111) was first exposed to 0.25 L furfural followed by 100 L H<sub>2</sub>, suppressed hydrogenation pathways to both furfuryl alcohol and methyl furan, affording a similar conversion and selectivity to that seen over clean Pt(111). The main product observed is furan desorbing at 291 K (Figure 6b). Figure 6c shows furfural conversion and selectivity as a function of furfural exposure over Pt(111) precovered with 100 L H<sub>2</sub>. The results are in excellent agreement with the reaction pathways proposed in Scheme 1. At low furfural exposures (corresponding to a high ratio of surface H(a):furfural) the stepwise hydrogenation of furfural to furfuryl alcohol, and its subsequent HDO to methyl furan, is favored. At high furfural exposures (a low surface H(a):furfural ratio),

insufficient surface hydrogen is available to further hydrogenate reactively-formed furfuryl alcohol, which hence becomes the dominant product, albeit in the latter scenario more furfural desorbs molecularly.

**Figure 6.** (a) TPRS for Pt(111) exposed to 100 L H<sub>2</sub> followed by 0.35 L furfural, (b) Reactively-formed furan production from furfural over Pt(111) surfaces, (c) Furfural reactivity over Pt(111) pre-exposed to 100 L H<sub>2</sub> as a function of furfural exposure. Molecular adsorption was performed at 140 K in all cases.

The preceding insight enables us to predict the selectivity to furfuryl alcohol during furfural hydrogenation (Figure 7); higher surface hydrogen concentrations encountered in gas phase furfural hydrogenation are expected to favor methyl furan relative to furfuryl alcohol, whereas the latter should be favored in the liquid phase. This is precisely as reported in the literature.<sup>11-12, 20, 59</sup>

**Figure 7.** Gas phase selectivities to molecular products for furfural with and without H<sub>2</sub> and for different orders of exposure to the two reactants

## Conclusions

The hydrogenation of furfural on Pt(111) was found to be highly sensitive to the conditions used to carry out the catalytic reaction in particular surface crowding and associated changes in the adsorption geometry. On clean Pt(111), furfural adopts a planar motif at low coverages and a more tilted geometry as the coverage is increased. The extent of decarbonylation to furan was found to depend strongly on the coverage (and therefore adsorption geometry): at low coverage the planar motif results in a much greater conversion to furan than occurs in the higher coverage tilted molecules. The formation of surface carbon and possible consequences for practical catalyst deactivation processes have also been investigated and discussed.

Control of the furfural coverage on the surface is critical to the reaction selectivity, with hydrogenation and hydrogenolysis being possible at higher coverages. A strong correlation between the reactivity of the Pt(111) surface with that of Pt dispersed systems was observed which enables the prediction of the activity and selectivity of Pt based catalysts under practical conditions in the liquid and the gas phase. The order in which the surface encounters hydrogen and furfural is

critically important. When furfural encounters a bare surface, it hinders the subsequent dissociative chemisorption of hydrogen and resulting hydrogenation activity. In contrast, when furfural encounters pre-adsorbed atomic hydrogen, furfuryl alcohol and methyl furan are produced; the former a product of direct furfural hydrogenation, and the latter a secondary product arising from the HDO of furfuryl alcohol (requiring a high ratio of surface H(a):furfural). At a low surface H(a):furfural ratio, insufficient surface hydrogen is available to further hydrogenate reactively-formed furfuryl alcohol, which hence becomes the dominant product. Our results indicate that control over the furfural adsorption geometry, and surface hydrogen concentration, are key considerations for the design and operation of practical Pt catalysts for this important bio-economy transformation.

## **Acknowledgements**

MJT would like to thank Aston University for a PhD studentship, KW thanks the EPSRC for funding under EP/K014676/1 and EP/K014749/1, LJ acknowledges funding of the China Scholarship Council (CSC). This work was supported by the European Research Council Advanced Grant MolArt (No. 247299). SKB thanks both the Durham University Addison Wheeler scheme

and the Leverhulme Trust's Early Career Fellowship scheme. GK acknowledges funding from the Royal Society and EPSRC (EP/M005186/2)
